Dampening inflammation

The adaptive immune response seems to dampen increases in Toll-like receptor (TLR)–mediated production of proinflammatory cytokines after burn injury. In the *Journal of Immunology*, Lederer and colleagues identify which adaptive immune cells mediate control of this inflammatory response. Burn-injured CD4-deficient splenocytes produced substantially more proinflammatory cytokines in response to TLR2 or TLR4 agonists than do burn-injured CD8-deficient and wild-type splenocytes, which produce amounts equivalent to each other after TLR stimulation. Specifically, adoptive transfer studies show that these Treg cells can also inhibit CD4+CD25+ T cell–induced inflammation in vivo. These data suggest that the various IL-6 signaling components control the balance between effector T cells and Treg cells in the lung.  

Good bugs

Although certain gut bacteria cause inflammatory diseases of the intestine, others, known as ‘probiotics’, are beneficial. In the *Journal of Immunology*, Di Giacinto et al. find that probiotics are beneficial in inflammatory bowel diseases because of the induction of Treg cells. In a recurrent colitis model, administration of probiotics leads to decreased IFN-γ production with a corresponding decrease in mortality. The protection against colitis, which is dependent on IL-10, is transferable with the lamina propria mononuclear cells (LPMCs). In the LPMC population is a subset of CD4+ T cells that expresses surface transforming growth factor-β (TGF-β) and is dependent on IL-10 for expansion. These regulatory cells are in turn dependent on TGF-β for their suppressive activity. Depletion of these regulatory cells from the LPMC populations abrogates their ability to transfer protection against colitis in host mice. Thus, probiotics suppress recurrent colitis through the generation of TGF-β-bearing regulatory cells.  

A positive function for IFN-γ

After immunization with collagen, DBA/1 mice succumb to an arthritis-like disease that is exacerbated in interferon-γ–deficient mice. In the *Arthritis Research & Therapy*, Kelchtermans et al. show depletion of CD4+CD25+ Treg cells from DBA/1 mice increases the severity of and hastens the onset of collagen-induced arthritis similar to the loss of IFN-γR expression in this mouse model. *Ifngrβ−/−* mice have numbers of Treg cells similar to those of wild-type mice, but after collagen immunization express less Foxp3 and show reduced suppressor activity. However, in *vitro* reconstitution assays show that this occurs because of an altered ‘instructive’ ability of antigen-presenting cells in the *Ifngrβ−/−* mice. The suppressive activity of *Ifngrβ−/−* CD4+CD25+ T cells is not reduced when wild-type antigen-presenting cells are used. Thus, IFN-γ provides a positive but indirect effect on eliciting peripheral Treg cell activity.

The two faces of IL-6

Interleukin 6 (IL-6) can signal via the membrane-bound IL-6 receptor (mIL-6R) or can signal in *trans* using a soluble IL-6 receptor (sIL-6R). In the *Journal of Clinical Investigation*, Doganci et al. investigate the possible function of these IL-6R signaling components in allergic asthma. Local blockade of sIL-6R in an experimental mouse model of asthma reduces T helper type 2 cytokine production in the lung, whereas local blockade of mIL-6R induces expansion of Foxp3+CD4+CD25+ regulatory T cell (Treg cell) populations. These Treg cells express a functional IL-6α receptor and show an increased ability to suppress target cells in *vitro*. In addition, an adoptive transfer model shows that these Treg cells can also inhibit CD4+CD25+ T cell–induced inflammation in vivo. These data suggest that the various IL-6 signaling components control the balance between effector T cells and Treg cells in the lung.  

**Treg cells for baby**

Mice seem to develop Treg cells soon after birth, but when humans begin to generate Treg cells is unclear. In the *European Journal of Immunology*, Cupedo et al. identify CD4+CD25+ cells in human fetal thymus as early as week 14 of gestation. These cells, which represent 15–20% of the thymic CD4+ population, also express several markers associated with regulatory activity, including GITR, Foxp3 and intracellular CTLA-4. Functionally, these cells show inhibitory activity in *vitro*. This thymic subset first appears at the double-positive stage, coinciding with expression of CD27. Peripheral Treg cells also express CD45RO, indicating that these cells have been activated in *vivo* by encounters with self or maternal antigens. Thus, human fetuses develop functional Treg cells early in gestation, thereby preventing potential lethal immune activity against themselves or their mothers.
