

IMMUNE REGULATION BY HELMINTH PARASITES: CELLULAR AND MOLECULAR MECHANISMS

Rick M. Maizels* and Maria Yazdanbakhsh[‡]

Immunology was founded by studying the body's response to infectious microorganisms, and yet microbial prokaryotes only tell half the story of the immune system. Eukaryotic pathogens — protozoa, helminths, fungi and ectoparasites — have all been powerful selective forces for immune evolution. Often, as with lethal protozoal parasites, the focus has been on acute infections and the inflammatory responses they evoke. Long-lived parasites such as the helminths, however, are more remarkable for their ability to downregulate host immunity, protecting themselves from elimination and minimizing severe pathology in the host.

T HELPER 1/T HELPER 2 CELL (T_H1/T_H2). A classification of CD4⁺ T cells on the basis of the patterns of cytokines that they secrete. T_H1 cells secrete large amounts of interferon- γ and associated pro-inflammatory cytokines. T_H2 cells secrete large amounts of interleukin-4 and associated cytokines that promote antibody production by B cells. T_H1/T_H2 cytokines can cross-regulate each other's responses. An imbalance of T_H1/T_H2-cell responses is thought to contribute to the pathogenesis of various infections, allergic responses and autoimmune diseases.

Helminths are complex eukaryotic organisms with large genomes, endowing some species with the ability to live for decades in the human host¹. Parasitic helminths infect more than two billion people in the world today, and cause marked morbidity and disability. In many infected individuals, parasitism leads to severe immunopathological complications such as granulomatous disease and organ failure. However, it is more common for the host–parasite interplay to seem harmonious, and clinically asymptomatic carriers act as long-term reservoirs for transmission (BOX 1). Although these infections might seem clinically to go unnoticed by the immune system, it is unlikely that the host remains ignorant of the parasite. Rather, highly effective mechanisms of immune subversion are clearly at play. In this review, we focus on new insights into immune regulation by helminths, and the growing number of new immunomodulatory molecules that are produced by parasites to exert their marked downregulatory effects.

Immunomodulation by helminths

The immunomodulatory effects of helminths are marked (FIG. 1). Both parasite-antigen-specific and more generalized levels of immune suppression are well documented in human studies. For example, patients with tissue helminth infections, such as schistosomiasis and filariasis, have diminished responsiveness to antigens

from the infecting parasite^{2–4}. More broadly, helminth infections are associated with downmodulated responsiveness in general, in some cases with measurable attenuation of responses to bystander antigens⁵, routine vaccinations^{6,7} or allogeneic tissue transplants⁸. Such 'spillover suppression' is related to the intensity of infection⁹, and extends to polyclonal responses to mitogens. Helminth infection can even have beneficial outcomes in reducing inflammatory disease caused by infection with *Helicobacter pylori*¹⁰ and *Plasmodium falciparum*¹¹.

A similar interplay between helminth-mediated downmodulation of the immune system and potential immune-mediated pathologies is now emerging with respect to diminished allergic manifestations in individuals with helminth infections. Schistosome-infected children have been shown to have lower levels of skin reactivity to allergens than uninfected classmates, indicating that the immune system might be influenced by the presence of parasites¹². These findings have led to a major shift in the hygiene hypothesis, the founding tenet of which was that T HELPER 2 (T_H2)-CELL mediated allergies would be counteracted by microorganisms that induce T_H1 cells. Because T_H2-inducing helminths (see later) are associated with the inhibition of T_H2-mediated inflammatory disease, mechanisms involving non-T_H1-cell populations, such as regulatory T (T_{Reg}) cells, are now being considered^{13,14}.

Marked polarization towards T_H2 cells. Helminths are the main examples of T_H2 -cell inducers in both humans and experimental models: high-level tissue eosinophilia, mucosal mastocytosis and, above all, the production of immunoglobulin E are observed^{15–18}. Generally, infectious-stage organisms induce the production of immediate type-2 cytokine responses, from both $CD4^+$ T cells and other sources, within 24 hours of entry into the host¹⁹. The drive towards T_H2 -cell polarization is so potent in many helminth infections that bystander proteins become targets for T_H2 -cell responses, including IgE antibodies^{20,21}, and naive T cells that express receptors for unrelated antigens differentiate to the T_H2 -cell phenotype²².

There are several interesting exceptions to the canonical rule of T_H2 -cell skewing by helminths. First, the initial infective stages of schistosomes (cercariae) stimulate T_H1 -cell responses in the mouse model. Only as infection progresses and eggs are released by fecund adults in the vasculature does the response switch to a T_H2 -cell response, driven by the schistosome-egg antigens¹⁸. Second, the newborn microfilarial stage of *Brugia malayi* promotes T_H1 -cell responses in mice, although

adult female worms, which release microfilariae *in vivo*, promote T_H2 -cell differentiation²³. Third, the gut nematode *Trichuris muris* (FIG. 2) induces T_H1 - or T_H2 -cell responses in mice of different strains²⁴. These will be fascinating subjects to study in terms of not only T-cell phenotype induction, but also maintaining subset dominance.

Additional crucial issues have yet to be resolved. What mediators or ligands from helminth parasites stimulate the immediate T_H2 -cell response? Which host-cell receptors and subpopulations are involved in generating and maintaining the T_H2 -cell phenotype? And, does the parasite or host benefit from the sustained T_H2 -cell bias that accompanies chronic infection with helminths?

T_H2 -cell inflammation — a case for regulation? A common over-generalization is that T_H2 -cell responses protect against helminth infection. Although human studies on schistosomiasis²⁵ and other helminths often have associated T_H2 -cell responses with protection from re-infection, there is also evidence that naturally immune individuals that are resistant to infection have

Box 1 | Immunology of human infections with *Schistosoma mansoni* and *Brugia malayi*

The exposure to these parasites can result in three broad outcomes that are associated with specific immune responses. One group of individuals are susceptible to infection and have immunological responses described as ‘modified T helper 2 (T_H2)-cell responses’. They have T_H2 -cell responses, with low levels of T_H1 cells, and express high levels of interleukin-10 (IL-10), which might indicate a strong regulatory T (T_{Reg})-cell activity. The T_H2 -type antibody profiles are dominated by the IgG4 isotype with relatively little IgE. These individuals often have clinically silent infections and are the main reservoir for onward transmission. At the other extreme, some individuals develop uncontrolled inflammatory (T_H1) disease. In schistosomiasis, strong immune responses can be mounted against eggs that are trapped in tissues, such as the liver or the bladder wall, leading to the formation of granulomas. Uncontrolled inflammatory responses, often characterized by type-1 responses in peripheral blood, are associated with hepatosplenic disease. There are only low levels of IgG4 but IgE responses are evident. In filariasis, strong type-1 immune responses are associated with lymphatic inflammation. This leads to pathological outcomes, such as elephantiasis, which is caused by the failure of lymphatic drainage and opportunistic secondary infection. In such cases, it would be expected that a low activity of regulatory T cells occurred. A third group of individuals seem to be resistant to infections. In this group, well-balanced immune responses would be characterized by the presence of measured T_H1 - and T_H2 -cell responses that are controlled due to the presence of T_{Reg} -cell activity. It is envisaged that the balanced T_H1 - and T_H2 -cell responses are of sufficient magnitude to kill the invading helminths. This is also reflected in a less skewed distribution of IgG4 and IgE isotypes in the T_H2 -type antibody profile.

Figure 1 | System-wide effects of helminth immunomodulation. A generic time course is postulated for the establishment of regulation over the course of an infection. During acute infection, antigen-specific T-cell responses are initially stimulated and cells proliferate in response to parasite antigens. With increasing exposure of the immune system to parasite antigens that are released from metabolically active worms, the immune system becomes increasingly hyporesponsive, first to specific parasite antigens and subsequently, when high worm burdens occur, to bystander antigens. Curative chemotherapy restores antigen-specific responses. The treatment of T-cell cultures with antibodies specific for interleukin-10 (IL-10) or transforming growth factor- β (TGF- β) can also rescue antigen-specific proliferation. The increased production of IL-10 and TGF- β that is responsible for inhibiting T-cell proliferation might be released either from antigen-presenting cells or T cells, and is postulated to be the result of downmodulatory molecules that are released from the worms to enhance their survival.

T_H1 -cell-dominated responses²⁶. A similar ambiguity exists in animal models, in which a clear protective role for the T_H2 -cell arm of immunity has been shown only for gastrointestinal nematode infections in mice^{24,27,28} (FIG. 2). In the gut environment, type 2 cytokines, including interleukin-3 (IL-3), IL-4, IL-9 and IL-13 act on mast cells, non-lymphoid epithelial cells and goblet cells to induce the expulsion of parasites through physiological reactions, such as mucus production and muscle hypercontractivity^{29,30}. Each parasite species is susceptible to different pathways of expulsion. So, mucosal mast cells underpin resistance to *T. muris*³¹ and goblet cells mediate resistance to *Nippostrongylus brasiliensis*²⁸, with both cell types dependent on the IL-4 receptor–STAT6 (signal transducer and activator of transcription 6) pathway for their activation³².

Many helminth parasites migrate through epithelial tissues, muscle and the lungs and here, few protective mechanisms depend on type-2-mediated effects³³. Exceptions do occur: for example, IL-5-overexpressing mice have large numbers of eosinophils and rapidly kill the larvae of *N. brasiliensis*³⁴ and *Strongyloides stercoralis*³⁵. However, eosinophils, in general, do not have a role in the expulsion of adult worms³⁶. So, distinct mechanisms are invoked not only to eliminate different species of helminth, but also to kill different life-cycle stages of the same species. Vaccination of mice can elicit protective responses to challenge with *Schistosoma mansoni*, and these are equally effective whether they are dominated by T_H1 - or T_H2 -cell responses³⁷. The strongest protective effect is observed in IL-10-deficient mice, in which both T_H1 - and T_H2 -cell responses develop to the highest level³⁸.

The argument has perhaps dwelled too long on an assumed pivotal balance between T_H1 - and T_H2 -cell responses³⁹. Several considerations now require a more sophisticated model. First, individual cytokines can have crucial effects in both type-1 and type-2 responses. For example, although tumour-necrosis factor (TNF) is regarded as a type-1 cytokine, it is required at an early stage in infection to synergize with the T_H2 -effector mechanism that expels the gut worm *T. muris*⁴⁰, and it also acts downstream of IL-4 to cause gut enteropathy in the T_H2 -type environment⁴¹. Second, although a combination of T_H1 - and T_H2 -cell responses is required for healthy resolution of infection⁴², an exaggerated response of either type is damaging to the host^{43,44}. And third, T-cell subsets can be further subdivided not only into variants of T_H1 and T_H2 cells, but also more broadly into T_{Reg} cells that can dampen both T_H1 - and T_H2 -cell activation^{45,46}.

However, although the T_H2 -cell response might have limited effects on parasite burden, it exerts an enormous influence on the survival of the host. T_H2 cytokines modulate excessive inflammatory reactions, preventing a runaway pathology⁴⁴. After 8 weeks of *S. mansoni* infection, wild-type (C57BL/6) mice enter a chronic phase of eggs accumulating in the liver, whereas IL-4-deficient mice die of inflammatory reactions to parasites⁴⁷. By autopsy, both groups were shown to have similar numbers of adult worms and eggs, but the IL-4-deficient animals had uncontrolled TNF production to which their demise is attributed. In this context, the T_H2 -cell response protects the host not from infection *per se*, but from the potential pathogenic damage caused by unrestricted T_H1 -cell-mediated inflammation^{18,48}. However, there are also circumstances in which the T_H2 -cell response itself causes pathology, as in the severe IL-4-dependent villous atrophy and crypt hyperplasia that accompanies *T. muris* infection⁴¹. Most markedly, the formation of granulomas in schistosomiasis, which triggers a lethal cascade in IL-4-deficient mice, is mediated by IL-13 (REFS 49,50) and can be blocked with soluble IL-13 receptor. So, the T_H2 -cell response itself has both pro- and anti-inflammatory functions in helminth infections, as is known for other important pathologies, such as asthma and autoimmunity.

When the host immune response is of the T_H2 type, the host must also ensure that only a regulated response is generated. Maintaining a limit on T_H2 -cell reactivity might be achieved through a homeostatic mechanism (the modified T_H2 -cell response) or by a more directed evolution of T_{Reg} cells. We suggest that if either of these mechanisms is deficient, pathology might be the result.

The modified T_H2 -cell response

A restrained form of the T_H2 -cell response can be envisaged with a less aggressive action. Such a phenotype has been classified as a 'modified T_H2 -cell response' in individuals who do not develop allergic disease despite high levels of exposure to allergen⁵¹. The main feature of the modified T_H2 -cell response is the uncoupling of specific IgG4 and IgE responses, with downregulation of the latter isotype. Both IgG4 and IgE class switching are

Figure 2 | **Rodent models of infection with intestinal nematodes.** For each of the three helminth species, different patterns of susceptibility are found, depending on the mouse strain and on the particular cytokines and T-cell responses that are induced. IL, interleukin; T_H , T helper.

known to be promoted by IL-4. However, it has been shown that IL-10 inhibits B-cell switching to IgE, while inducing the production of IgG4 by the same cells⁵². IL-10 is a downmodulatory factor in allergic disease, and might be produced by the modified T_H2 cells themselves or by other populations, such as antigen-presenting cells (APCs), that function to induce the modified T_H2 -cell phenotype.

The literature on helminth infections provides many examples that are consistent with T_H2 -cell modification. In human cases of filariasis pathology (such as elephantiasis), parasite-specific responses comprise both IgE and IgG4 antibodies. By contrast, the more common asymptomatic, but highly infected microfilaraemic carriers have high levels of specific IgG4, but lower levels of IgE⁵³. So, in both allergy and helminth infection, high antigen loads are associated with the modified T_H2 -cell phenotype. A further modification of the T_H2 type involves downregulated IL-5 responses to antigen, which would reduce the involvement of eosinophils in type-2-mediated inflammation^{4,54,55}.

In most other helminth infections, evidence of modulated T_H2 -cell responses can also be found. For example, studies of granuloma formation in mouse schistosomiasis show a regression in the intensity and size in later infection, a downmodulatory process that can be transferred by T cells to a more-recently infected animal⁵⁶. In the schistosome-infected liver, expression of the decoy receptor IL-13R α 2 is induced, which blocks IL-13-dependent fibrotic reactions⁵⁷. As IL-13 itself is an inducer of IL-13R α 2, a feedback loop seems to act entirely within the T_H2 -cell response to limit potential damage. Although the IL-13 regulatory circuit has not been linked directly to later downmodulation of granuloma size, it is a good example of modification and, possibly, maturation of the T_H2 -cell response.

Can modified T_H2 -cell responses alter the outcome of infection in rodent model systems? Some apparent paradoxes indicate so. For example, a strong T_H2 -cell response occurs in all strains of mice that are infected with *Heligmosomoides polygyrus* (FIG. 2). Many strains, however, fail to expel the parasite, indicating either that the T_H2 -cell response is adopting a modified form, or

that another mode of the immune system (such as T_{Reg} cells) is intervening to prevent expulsion. A similar situation occurs during infection with the tissue filarial nematode *Litomosoides sigmodontis*, in which C57BL/6 mice mount an IL-4-dependent protective T_H2 -cell response, yet the T_H2 -cell response of BALB/c mice cannot kill the parasites⁵⁸.

Regulatory T cells

Longitudinal analyses in experimental infections, as well as immunoepidemiological studies in human populations, point to a scenario in which early immune reactivity undergoes gradual attrition in terms of parameters such as T-cell proliferation and inflammatory-cytokine production^{55,59} (FIG. 1). Most strongly associated with this loss of responsiveness, both antigen-specific and polyclonal, are the cytokines IL-10 and transforming growth factor- β (TGF- β), indicating that regulatory populations are activated during infection. In *S. mansoni* infection of mice, for example, initial T_H0/T_H1 -cell responses give way first to pro-inflammatory T_H2 -cell responses, followed by a decline in parasite-specific T-cell responses in a more regulated environment.

The prominence of IL-10 as a crucial mediator of regulation in parasite infections has long been recognized⁶⁰, particularly for its role in attenuating pathogenesis. Studies with IL-10-deficient mice show a failure to control pathological reactions, with fatal results in infections with *T. muris*⁶¹, and increased mortality in infections with *S. mansoni*⁶². In one study, IL-10-deficient animals fail to enter the late downmodulating phase in which the size of liver granulomas decreases⁶³.

In human filariasis, heavily infected individuals have constitutively high IL-10 levels⁶⁴ and IL-10 messenger RNA production, which is inversely correlated with T-cell proliferation. Filarial-specific T-cell proliferation can be restored *in vitro* by antibodies specific for IL-10 and/or TGF- β ^{2,65}. In onchocerciasis^{55,66} and schistosomiasis, similar reversals are observed^{67,68}. Similarly, IL-10-specific antibody rescues interferon- γ (IFN- γ) responses to schistosome antigens^{68,69}. These studies did not, however, address whether the IL-10 response is antigen specific.

Do T_{Reg} cells participate in the host response to helminths? Preliminary evidence to support this idea is now emerging. In onchocerciasis, parasite-antigen-specific T-cell clones that secrete IL-10 and TGF- β , but not IL-2, were isolated from a patient whose peripheral T cells were hyporesponsive⁶⁶. Similar T-cell clones could also be recovered from the onchocercoma — the capsule around the local site of *Onchocerca* adult worms — which were cytotoxic T lymphocyte antigen 4 (CTLA4) positive and functioned to inhibit the proliferation of bystander T cells⁷⁰. Flow cytometric analysis of peripheral T cells in lymphatic filariasis has indicated the expansion of CTLA4⁺ T-cell populations in individuals with suppressed T-cell function, and showed that CTLA4-specific antibodies increased the production of IL-5 by T cells in response to antigen *in vitro*⁷¹. In our own work on mouse filariasis, high numbers of CTLA4⁺CD4⁺ T cells, also expressing the

T_{Reg} -cell-associated marker GITR (glucocorticoid-induced TNF receptor-related protein)⁴⁵, accumulate around the site of infection, whereas neutralization of T_{Reg} cells with GITR-specific or CD25-specific antibodies renders mice more resistant to infection with *L. sigmodontis* (M. Taylor, L. Le Goff, E. Malone, A. Harris, J. E. Allen and R. M. M., unpublished observations).

The general concept for T_{Reg} cells has been that they are autoreactive thymic emigrants, otherwise known as 'natural' T_{Reg} cells⁷². However, the need to control responses to external antigens such as commensal flora⁷³ begs the question of whether naive T cells can selectively mature into T_{Reg} cells in the periphery. The existence of T_{Reg} cells that recognize bacterial^{74,75} and protozoal⁷⁶ antigens underscores this question. Can helminths activate pre-existing (natural) T_{Reg} cells, as indicated by evidence of a role for T_{Reg} cells immediately after infection? Parasites could also convert naive T cells into either antigen-specific or antigen non-specific T_{Reg} cells through unknown pathways. With increasing knowledge of the molecular products of helminths (as described later), and advances in the characterization of T_{Reg} cells, these questions will be answered in the near future.

Regulatory accessory cells? Antigen-presenting dendritic cells (DCs) make the first encounter with a parasite, reacting either to specific or generic signals to polarize T-cell responses⁷⁷. Arguably more important in the context of chronic helminth infection is that accessory-cell populations can mediate modulatory functions on a

steady-state basis. Suppressive adherent cells were identified 20 years ago in long-term infected humans⁷⁸ and animals⁷⁹, and subsequent studies have shown that the production of IL-10 by macrophages is one pathway by which this suppression can take place^{80–82}. Although accessory cells, such as macrophages, express no antigen-specific receptors, their modulatory effects can often be imposed on the antigen-specific response by co-localization in a microenvironment that is occupied by responding lymphocytes.

An important advance has been the discovery of a new form of macrophage that arises in nematode infections, which operates through an IL-10-independent pathway^{82,83} as summarized in FIG. 3. First found in the peritoneum of mice infected with *B. malayi*, similar cells occur in animals that are exposed to other nematodes and their secreted products⁸⁴. Nematode-elicited macrophages (NeMacs) are larger and more multivacuolar in morphology than other macrophages, and have a markedly different profile of gene expression. In place of inflammatory nitric-oxide production, these cells upregulate the expression of arginase (which competes for the substrate of nitric-oxide synthase) and two new proteins YM1 and FIZZ1 (REFS 85,86). Because YM1 has also been identified as eosinophil chemotactic factor, this might explain why the recruitment of NeMacs is accompanied by a localized infiltration of eosinophils. These macrophages are markedly cytostatic, preventing the proliferation of non-lymphoid cells, as well as T cells, and they act through a contact-dependent mechanism that is independent of known inhibitors such as nitric oxide, prostaglandins or the cytokines IL-10 and TGF- β ⁸⁷. Moreover, NeMacs induce the differentiation of naive mouse T cells into T_{H2} cells⁸⁸ and can perhaps be considered as type-2 macrophages. Overall, the suppressive NeMacs are an important *in vivo* example of alternatively activated macrophages⁸⁹.

In their first encounter with DCs, helminths seem to take a more stealthy approach. Mouse bone-marrow-derived DCs stimulated by helminths show limited upregulation of CD80, CD86 and MHC class II expression in comparison to expression induced by bacterial stimulants^{90,91}. Data from experiments using microarray technology indicate that few of the lipopolysaccharide (LPS)-inducible genes are switched on by DCs that are exposed to *N. brasiliensis*-derived T_{H2} -cell-stimulating antigens (A. Balic and R. M. M., unpublished observations). It is possible that these immature DCs might bias responses towards the T_{H2} -cell response. However, in human DCs that are matured in the presence of LPS, schistosome-egg antigens do not inhibit the upregulation of expression of these markers and yet the DCs have potent T_{H2} -cell-promoting capacity, and so are referred to as DC2s (REF. 92). One notable feature of DC2s is the expression of OX40 ligand, which is potentially relevant as ligation of OX40 amplifies T_{H2} -cell differentiation⁹³. Because DCs are not an essential source of either IL-4 or IL-10 in the induction of helminth-skewed T_{H2} -cell responses⁹⁴, the search is still under way for intermediary molecules. One candidate is CCL19 (macrophage inflammatory protein 3 β , MIP3 β), the

Figure 3 | Alternatively activated macrophages. Helminth infections in the peritoneal cavity — for example with *Brugia malayi*, *Nippostrongylus brasiliensis* and *Toxocara canis* — elicit a new phenotype of macrophage, nematode-elicited macrophages (NeMacs), which are similar to alternatively activated or type-2 macrophages^{82,86}. Among their features are: marked suppression of target cell proliferation through a contact-dependent mechanism that does not require interleukin-4 (IL-4), IL-10, prostaglandins or nitric oxide; induction of T helper 2 (T_{H2})-cell differentiation of naive T-cell receptor-transgenic T cells; attraction of eosinophils; and a unique profile of gene expression that includes arginase and two new genes, *YM1* and *FIZZ1*. One recombinant protein from *B. malayi*, the cytokine mimic macrophage-migration inhibition factor 1 (*Bm*-MIF1), induces the expression of YM1, as well as eosinophilia. This effect is lost in a *Bm*-MIF1 mutant in which a single amino acid has been altered (proline to glycine)¹²². So, *Bm*-MIF1 might be a necessary, but not sufficient, stimulus for macrophages to adopt the alternatively activated phenotype.

expression of which is induced in DCs by the mosquito-borne infective L3 stage of *B. malayi*, but not by microparasites⁹⁵, and has been reported to promote the synthesis of IL-10 by human leukocytes.

DCs can, under certain conditions, differentiate into strong inducers of T_{Reg} cells⁷⁵. For example, if lipid fractions from *S. mansoni* are present during the maturation of human DCs, the DCs become conditioned to induce regulatory activity (such as IL-10 production) by naive T-cell populations⁹⁶. So, regulatory accessory cells can develop under the influence of defined parasite molecules, and it seems that helminths might induce T_{Reg} cells through specific APC subsets. FIG. 4 illustrates how the regulatory environment that surrounds helminth infections might be envisaged.

Parasite immunomodulators

In this section, we examine individual helminth components, in the context of particular roles in immune evasion. We then discuss more generally whether the regulatory mechanisms in the immune system are reacting to selected molecular patterns of helminths, or if

parasites have evolved to direct regulation for their own ends. Our emphasis is largely, but not entirely, on products that are secreted by parasites or otherwise made available to the host immune system by living worms (FIG. 5). This focus helps select from the large genomes of helminths (~20,000 protein-coding genes⁹⁷) those proteins with maximum impact on host biology that are likely to have evolved, in a controlled manner, precisely to modulate and regulate the host immune system.

Interference with antigen processing. Antigens from extra-cellular helminth parasites are, it is presumed, presented to the immune system through the MHC class II pathway, with crucial processing steps controlled by intracellular proteases. The filarial nematode *B. malayi* secretes a cysteine proteinase inhibitor (cystatin, *Bm*-CPI2), which interferes with two classes of protease in the MHC class II pathway, the papain-like cathepsins B, L and S and the legumain-type asparagine endopeptidase. In an experimental model, these properties enable CPI2 to block the presentation of peptides that are derived from exogenous tetanus toxoid by human B cells⁹⁸. Similar inhibitors have been described from *Onchocerca volvulus*⁹⁹ and *N. brasiliensis*¹⁰⁰. Interestingly, nematode cystatins are homologues of mammalian cystatin C, which is highly expressed by immature DCs, then down-regulated during DC maturation to allow the transport of mature MHC class II complexes to the cell surface¹⁰¹. Parasite cystatins could, therefore, maintain DCs in an immature state in which their antigen-presentation capacity is compromised. Consistent with this hypothesis, the *O. volvulus*-derived cystatin (onchocystatin) reduces the expression of HLA-DR by human monocytes after 72 hours of co-culture⁹⁹.

Eukaryotic cystatins share a conserved papain-inhibiting loop that blocks cathepsins B, L and S. Only certain mammalian cystatins (including cystatin C expressed by DCs) have a second inhibitory site on the opposite face of the molecule, which inactivates asparagine endopeptidase. Notably, this motif is present in the filarial cystatins, and inhibition of asparagine endopeptidase is abolished by site-directed mutagenesis of this motif (J. Murray, B. Manoury, C. Watts and R. M. M., unpublished observations). Because *Caenorhabditis elegans*-derived cystatins inhibit cathepsins, but not asparagine endopeptidase, the filarial homologues might have acquired, through convergent evolution, a new inhibitory property that imitates that of the host and markedly increases the potency of the inhibitor by allowing it to block simultaneously two different classes of protease that are essential for antigen processing.

Modulation of antigen-presenting cells. The effects of cystatins extend beyond the direct inhibition of processing enzymes, as, in the case of onchocystatin at least, they can modulate T-cell proliferation and elicit the upregulation of IL-10 expression^{99,102}. So, the cystatins might have an important role in directing and maintaining the altered T-cell phenotype in onchocerciasis. Other modulators from helminths, such as the prostaglandins and other derivatives of membrane arachidonic

Figure 4 | The regulatory environment that we propose might develop during helminth infection. a | The entry of a parasitic helminth leads to the activation of dendritic cells (DCs) in the peripheral tissues; these cells will express co-stimulatory molecules and react to polarizing signals from helminths. It is known that they initially activate naive T cells to become T helper 2 (T_{H2}) cells. It is also possible that crossreactive helminth antigens might stimulate the involvement of natural regulatory T (T_{Reg}) cells. The early involvement of T_{Reg} cells (natural and/or adaptive) is thought to impede T_{H2}-cell responses, such as interleukin-5 (IL-5)-dependent eosinophil activation, and safeguard against excessive T_{H2}-cell responses. **b** | With increasing levels of parasite antigens, we postulate that a stronger regulatory network might be established through antigen-specific (adaptive) T_{Reg} cells. At this chronic stage of infection, macrophages are known to acquire an alternatively activated phenotype (AAM) that can suppress T-cell proliferation and promote the development of modified T_{H2} cells. The interactions of DCs and newly differentiating macrophages with T cells in chronic infection are less clear, but the effector arms of the immune system remain in a modified state with, for example, the reduced production of IL-5, and high levels of IL-10 (produced by adaptive T_{Reg} cells), which switches B-cell responses to IgG4 and not IgE, and transforming growth factor-β (TGF-β), which mediates cellular hyporesponsiveness.

Figure 5 | Immune modulators. Parasite-derived immune modulators function at several levels on crucial immune regulatory cells. Cytokine mimics, such as macrophage-migration inhibition factor (MIF) and transforming growth factor- β (TGF- β), that are present in helminths such as *Brugia malayi* can modulate macrophage function and lead to the induction of T helper 2 (T_H2) cells and immune suppression. Non-protein signature molecules (for example, from *Schistosoma mansoni*) such as phosphatidylserine (PS) and lyso-PS, phosphorylcholine and a range of glycans (such as di-*N*-acetyl-difucosylated lactose, lacto-*N*-fucopentaose III and lacto-*N*-neotetraose) can interact with dendritic cells and result in the induction of both T_H2 - and regulatory T (T_{Reg})-cell phenotypes. Helminths also produce prostaglandins PGD₂ and PGE₂, which can have similar effects on accessory cells (not shown). Direct interference with antigen presentation by parasite-derived cystatins (such as CPI2 from *B. malayi* and onchocystatin from *Onchocerca volvulus*) prevents T-cell activation both at the level of T-cell receptor engagement by peptide-MHC complexes (by inhibiting proteases involved in antigen presentation), and by enhancing the production of interleukin-10 (IL-10) by accessory cells.

acid, might have similar roles. For example, the 5-lipoxygenase-dependent production of lipoxin A4 (LXA4) has recently been identified as a crucial step in blocking the production of IL-12 by DCs¹⁰³. Prostaglandins — products of an alternative metabolic pathway from arachidonic acid through cyclo-oxygenases — also influence DCs and macrophages. Prostaglandin E₂ (PGE₂), and more recently PGD₂, are known to inhibit the production of IL-12 by DCs and so act as T_H2 -cell-promoting factors¹⁰⁴, although PGD₂, in particular, also inhibits the efferent migration of skin Langerhans cells after exposure to schistosomes¹⁰⁵. So, the fact that helminths, such as *Taenia taeniaeformis*¹⁰⁶ and *B. malayi*¹⁰⁷, synthesize and release PGE₂ (other metabolites have yet to be assayed) provides a direct route for immunomodulation of APCs in these parasitic infections. Interestingly, the schistosome vaccine candidate, known as glutathione-S-transferase, is now understood to be a PGD₂ synthase, produced by skin-invading schistosome larvae. As noted earlier, PGD₂ would have the effect of blocking the migration of Langerhans cells to the draining lymph nodes, thereby inhibiting a crucial step in the initiation of immunity¹⁰⁵.

Prostaglandins are not the only helminth-encoded product to affect the activity of APCs. The phosphorylcholine-bearing filarial secreted product ES62 also has the effect of desensitizing mouse peritoneal macrophages to subsequent IFN- γ /LPS-induced production of

IL-12, thereby skewing against a T_H1 -cell response¹⁰⁸. Two of the main glycans of schistosome eggs, lacto-*N*-fucopentaose III and lacto-*N*-neotetraose, are also highly active in inducing macrophages to produce IL-10 and adopt a suppressive phenotype that can block T-cell proliferation^{109,110}. Interestingly, both glycans are shared with the mammalian host as they are present in human milk, raising the as-yet-untested possibility that the parasite is engaging in molecular mimicry for the purposes of immune downregulation.

The abundant larval transcript (ALT) proteins are parasite-specific products of *B. malayi*, which are represented by 5% of the complementary DNA of the invading larva and have no similarity with host proteins. To test whether these are immune-evasion products, we transfected ALT-encoding transcripts into the protozoan parasite *Leishmania mexicana*, and showed that expression of ALT proteins conferred greater infectivity of bone-marrow-derived macrophages *in vitro* and accelerated disease in mice *in vivo* (N. Gomez-Escobar, C. Bennett, L. Prieto-Lafuente, T. Aebischer, C. C. Blackburn and R. M. M., unpublished observations). It, therefore, seems that the ALT proteins are produced by the mosquito-stage parasite and are poised to compromise cell-mediated immunity in a manner that is advantageous to parasite survival.

DCs have been shown to react with defined helminth molecules in two systems. In one, filarial ES62 induces mouse DCs to differentiate towards the DC2 subset, as judged by the cytokine profile of co-cultured naive T cells¹¹¹. As with the studies using schistosome antigens discussed earlier, this functional property was acquired without notable changes in the cell-surface phenotype of the DCs.

In the second model, the lipid fractions from *S. mansoni* adult worms and eggs were tested on human DCs. Interestingly, material from either life-cycle stage that contained phosphatidylserine resulted not only in DC skewing towards T_H2 -cell induction (in a manner similar to PGE₂), but also stimulated the development of IL-10-producing T_{Reg} cells⁹⁶. In this fraction, it was the lysophosphatidylserine family of molecules (lyso-PS) with acyl chains that are not found in mammalian lyso-PS that were responsible for the induction of T_{Reg} cells. This lipid species (lyso-PS) activates DCs through Toll-like receptor 2 (TLR2), providing the first clear evidence that TLRs are involved in the recognition of helminths. In addition to the lyso-PS-TLR2 interaction, many other ligand-receptor pairs are likely to exist between helminths and the immune system. For example, binding between *S. mansoni*-derived Lewis x and DC-SIGN (DC-specific intercellular adhesion molecule-grabbing nonintegrin) — a member of the C-type lectin family that is expressed by DCs — has recently been reported¹¹². As innate immune cells express a wide variety of C-type lectins, and some helminths that reside in the tissues secrete functional lectins of the same family, there might be a complex interplay between host receptors, parasite glycans and parasite competitor or decoy molecules¹¹³.

Figure 6 | Blocking efferent immune mechanisms and effector cells. Helminths that reside in the tissues (such as many larval forms and adult worms of *Onchocerca*) exert a strong anti-inflammatory effect. This might be explained by interference with crucial steps of the immune response, such as extravasation (mediated by leukocyte recognition of endothelial selectins — an interaction that might be blocked by parasite lectins and glycans), chemokine attraction (blocked by parasite protease degradation¹²⁶), release of host proteases (inhibited by helminth serpins¹²⁸), and potentially lethal attack with reactive nitrogen and oxygen intermediates (NO and H₂O₂) by eosinophils and other cells (inhibited by antioxidants such as glutathione peroxidase, thioperoxidase, superoxide dismutase and glutathione-S-transferase¹⁴⁷).

Cytokine interference and mimicry. Cytokines and chemokines are crucially involved in both innate and adaptive immune responses, so it is not surprising that pathogens have evolved a myriad of strategies to interfere with their function. The two clearest examples in helminths are in gene families that are shared between all multicellular organisms, indicating that helminth parasites have adapted ancestral genes that are present in free-living antecedents to evolve proteins that can interact functionally with host cytokine receptors.

The first helminth cytokines to be found were the homologues of TGF- β expressed by the filarial worm *B. malayi*^{114,115}. Two TGF- β -like proteins are described, one of which (*Bm*-TGH2) is maximally expressed at the arrested microfilarial stage, is secreted by cultured parasites and binds to the mammalian TGF- β receptor¹¹⁵. Interestingly, both filarial parasites¹¹⁶ and schistosomes¹¹⁷ encode members of the TGF- β receptor family, and a TGF- β -like ligand has been noted in the cestode *Echinococcus granulosus* (C. Fernandez, K. Brehm and R. M. M., unpublished observations), so that all helminth groups might have the potential to exploit TGF- β -mediated immune downregulation.

The second set of helminth cytokines is comprised of the macrophage-migration inhibition factors (MIFs), which are now known to be produced by numerous nematode parasites including *B. malayi*^{118–120}. Mammalian MIF is a small cytokine with enigmatic properties: synthesized widely by nonhaematopoietic cells, it acts as a pro-inflammatory cytokine in acute settings such as septic shock, inducing the production of TNF by macrophages, for example. *B. malayi*-encoded MIFs have the same effect on human monocytes as mammalian MIF¹²⁰, which seems to be inconsistent with the

anti-inflammatory phenotype of the parasite. Most remarkably, *B. malayi*-encoded MIF2 was shown by analysis of its crystal structure to be markedly similar to human MIF, and both helminth and human MIF have enzyme activity (dopachrome tautomerase) that is abolished by mutation of a proline residue to glycine (the MIF1G mutant)¹²⁰. We hypothesized that the effect of *B. malayi*-encoded MIF *in vivo*, where it is continuously released, might, in fact, be anti-inflammatory, and molecular studies of mammalian MIF show that it can activate an anti-inflammatory pathway through the JAB1 transactivating factor¹²¹. To support this contention, we found that mice given repeated injections of *Bm*-MIF1 upregulate the level of YM1 transcripts associated with alternative activation of macrophages, and have a mild eosinophilia; the *Bm*-MIF1G mutant had no such effect¹²².

Additional cytokine mimics are likely to be found only by functional assays. For example, an IFN- γ -like protein was reported to be secreted by *T. muris*¹²³. As this parasite is expelled by T_H2-cell-derived IL-4 (FIG. 2), such a product is likely to prolong its survival. If there are replica IFN- γ molecules, it would be expected that mimics of functional IL-10 have yet to be discovered in helminth genomes, albeit not recognizable at the sequence level. Similarly, chemokine mimics might be too difficult to identify by sequence. However, in a functional test, a neutrophil chemoattractant with chemokine-like binding properties has been found in *Ascaris suum*¹²⁴. As bioinformatic techniques, such as structural prediction, become more sophisticated, it might be possible to select candidate genes from the ongoing genome sequence projects for functional assays of this nature.

Blocking of effector mechanisms. Despite the measures described earlier to downmodulate host immunity, it is essential for a successful parasite to have ‘last-ditch’ defence mechanisms against immune attack. Several such tactics have now been described (FIG. 6). For example, the host chemoattractant platelet activating factor (PAF) is targeted by a complementary enzyme, PAF hydrolase, encoded by *N. brasiliensis*¹²⁵, and eotaxin is degraded by proteases from hookworms¹²⁶, so inhibiting the recruitment of immune cells from the blood. The proteases encoded by the host, such as neutrophil elastase and cathepsin G, are inhibited by the serpin that is released from bloodstream microfilariae of *B. malayi*¹²⁷, and serpins from many other helminth parasites are mainly expressed in similar circumstances¹²⁸. Antibodies are inverted by Fc-binding molecules on the surface of schistosomes¹²⁹, and the activation of complement is inhibited in infection with *E. granulosus* by uptake of the host inhibitory factor H onto the hydatid cyst wall¹³⁰. Reactive oxygen intermediates are dealt with by parasite surface enzymes such as glutathione peroxidase and superoxide dismutase¹³¹. Now that genetic tools, such as RNA interference, are beginning to be applied successfully to parasitic helminths^{132–134}, we can begin to place these diverse products in a functional hierarchy and understand the context for their immunosuppressive roles.

Have helminths evolved to stimulate T_H2 cells

The fact that T_H2-cell responses in mice not only protect the host from the pathological consequences of schistosomiasis, but also promote parasite transmission in terms of the egress of eggs into the intestinal lumen, indicates that the switch to T_H2 cells can benefit both partners in this host–parasite relationship. Extending this argument to the human context, a study reported that schistosome-infected individuals with low CD4⁺ T-cell counts owing to HIV co-infection have lower rates of egg excretion¹³⁵. Does the T_H2-cell response simply reflect an appropriate form of host recognition of helminth parasites or, more controversially, have parasites selectively evolved to stimulate T_H2-cell responses for their own advantage. If the former, it might be predicted that common pathogen-associated molecular patterns (PAMPs) will exist for helminths (or at least separately for the three principal phyla of cestodes, nematodes and trematodes). If the latter, then the repeated evolution of parasitism in different lineages of helminth organisms might have resulted in specific and unique molecular strategies for the stimulation of T_H2 cells in different taxonomic branches.

The search for a helminth equivalent of bacterial LPS or viral double-stranded RNA, possibly acting through a TLR form attuned to multicellular parasites, is one of popularity at present. However, so far, we have identified no generic motif that specifically marks eukaryotic pathogens. Some interesting possibilities remain to be studied, particularly among parasite carbohydrates, and a mechanism that recognizes, for example, the absence of sialic acid from lower invertebrate glycans might also operate. Moreover, the apparent absence of DNA

methylation in lower vertebrates (experimentally shown for *S. mansoni*¹³⁶) implies that resulting CpG motifs could trigger pro-inflammatory responses through TLR9 (REF. 137). Although DNA release would only be expected following death of a parasite, attrition of a proportion of incoming larvae always occurs, and so there is opportunity for an interaction at this level.

The argument against a generic helminth PAMP might rest on the various strategies for the induction of T_H2 cells that are already apparent among parasitic helminths, including the expression of unique proteins that stimulate the production of IL-4. Although the free-living nematode *C. elegans* elicits a T_H2-cell response if injected into mice, its related parasites carry out this feat more potently (J. E. Allen, personal communication). It is possible that from an inherent tendency towards a T_H2-cell response, parasitic species might have amplified this capacity to its present level in which secreted proteins from one T_H2-driving parasite (*N. brasiliensis*) can act as an adjuvant for T_H2-cell responses¹³⁸. One of the candidate glycan motifs that might give a molecular stamp to helminths is thought to be the α 3-fucosylation of a chitobiose (GlcNac₂) core¹³⁹. So, DCs pulsed with fractions containing this motif or the β 2-xylosylated core sugar drive strong T_H2-cell responses in mice¹⁴⁰. However, the same structures are found not only in *C. elegans*¹³⁹, but also in host Lewis x, implying that additional structural factors must lend specificity and intensity to the T_H2-cell response to helminth glycans.

Taking *S. mansoni* as another example, proteins, glycans and lipoconjugates can all induce T_H2 cells. One recombinant protein, IPSE, which is a prominent secreted egg product, can stimulate the release of IL-4 by human basophils¹⁴¹. IPSE seems to bind IgE present on the cell surface of basophils, irrespective of antigen specificity, and activates cells by crosslinking. A second recombinant protein, TCTP, also activates basophils in terms of histamine release, although the release of IL-4 was not measured¹⁴². Notably, from the same source, are the host-like glycans, such as the Lewis x-related carbohydrate lacto-N-fucopentaose III, which when conjugated to human serum albumin, elicits strong T_H2-cell recall responses (IL-4, IL-5, IL-10 and IgE) in mice¹⁴³. In addition, the lipid fraction from the same eggs induces T_H2-cell differentiation, in a manner that is distinct from the stimulation of T_{Reg} cells, as only the latter depends on TLR2 (REF. 96). Overall, the example of *S. mansoni* argues strongly that helminths have evolved directed mechanisms for the induction of T_H2 cells, rather than passively retained generic features from which the host selects differentiation of this pathway.

Regulatory circuits — a balanced equilibrium?

The survival of helminth parasites indicates their success in outmanoeuvring the immune system, but we should also note that they frequently succeed in achieving some form of balanced parasitism in which transmission is maintained and acute morbidity avoided. This ideal, homeostatic state almost certainly requires an environment rich in regulatory mechanisms, be they

IDIOTYPIC NETWORK

The antigen-binding site of an antibody is an idiotype. As an immune response develops and clonal expansion of B cells occurs, the prevalence of this previously rare idiotype increases and can lead to the development of an anti-idiotypic T- and B-cell response.

T_{Reg} -cell pathways or many of the other modulatory interactions discussed earlier.

We envisage a scenario with both mini-regulatory circuits, such as the IL-13 feedback loop, which produces soluble decoy IL-13 receptor molecules, and more widespread downregulation mediated by systemic production of IL-10 and TGF-β. Between these extremes, there might be localized regulators, such as the DC populations in the draining lymph nodes and the alternatively activated NeMacs that are induced in *B. malayi* infection. Of course, there are in addition many other, independent modulatory connections, and in a clinically asymptomatic individual, it is expected that a combination of these mechanisms might be required, acting together to prevent the pathogenic overshooting of the host immune response.

At this stage, however, it is tempting to suggest that T_{Reg} cells will prove to be intimately involved in the immunobiology of helminths. Certainly, the effects of IL-10 extend widely to antibody isotypes, T-cell phenotypes and APC functions, all of which match well with the observed immunological status of typical patients with chronic schistosome or filarial infections. More generally, the ‘regulatory environment’ model (FIG. 4) revises the hygiene hypothesis, to indicate that both T_H2-mediated allergies and T_H1-mediated autoimmune diseases can be coordinately controlled by the regulatory

arm of APCs and T cells. Moreover, the model can explain the phenomenon of ‘wormy individuals’, who make up the small percentage of individuals in endemic populations who have particularly high worm burdens. Perhaps the wormy individuals have the strongest regulatory network, resulting in an immune system less prone to allergy and autoimmunity, but more likely to harbour heavy helminth infections.

If there are, as we suggest, regulatory wheels within wheels, any regulatory mechanism must require intricate tuning of parasite molecular structures to host receptors and ligands. No doubt, this will have evolved over long periods of time, and in most cases confer strict host specificity on each species of parasite. Moreover, the areas we have discussed are far from exhaustive. For example, a detailed study of schistosomiasis has provided strong evidence for an IDIOTYPIC NETWORK that regulates hyperresponsiveness¹⁴⁴, there is evidence that neonatal exposure to parasites induces susceptibility to infection in later life¹⁴⁵, and there is growing interest in the pro-inflammatory effects of endosymbiotic bacteria found in most filarial parasites¹⁴⁶. Future investigations will allow us to integrate these varying strands of regulation and counter-regulation, and thereby devise means of intervention not only to prevent parasite infestation and pathogenesis in particular, but also immunopathological and inflammatory disease in general.
